Commentary on PGIP

[Version 1.30, 2007/07/11 10:28:22, LATEX: August 28, 2009]

David Aspinall

Christoph Lüth

August 28, 2009

PGIP is the *Proof General Interaction Protocol*, a message passing protocol for communicating proof components, primarily interactive theorem provers and their interfaces.

This document gives commentary on the definition of PGIP, version 2.0.X. The commentary is intended as a set of notes to help implementors of PGIP-enabled components; it does not form a complete description or motivation for the protocol. The RELAX-NG schemas for PGIP messages and the PGML markup language are given in the appendix.

Warning! this is an evolving draft version, some details in the text may be out-of-step with schemas shown in the appendix and with the latest implementations. And you may not be looking at the latest version of this document! If in doubt, please contact the authors before relying on details here.

1 Basics

1.1 Overview

- 1. PGIP is an interaction protocol between different components of an architecture to support interactive proof development, and a markup language for proof scripts in such an environment.
 - Fig. 1 shows the corresponding system architecture.

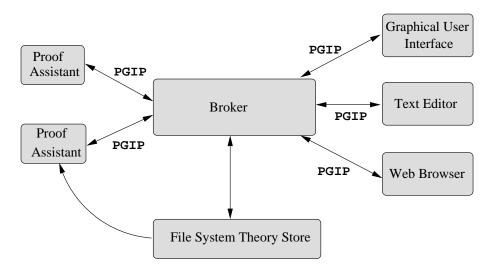

Figure 1: PG/Kit system architecture

- 2. The PGIP protocol is intended as a mechanism for conducting interactive proof using PGIP-enabled software components. The aim of interaction is to produce one or more **proof scripts**.
- 3. A proof script has a textual representation as primary and resides in a file. Proof scripts are written in the prover's native language.
- 4. Part of PGIP serves to make explicit the structure which is normally implicit in the proof script, by requiring the proof assistant to add certain XML mark up. The basic invariant is that by forgetting all the PGIP structure (applying the trivial forgetful stylesheet, if you will) we get back the original proof script.

1.2 PGIP communication

- 1. PGIP components connect to a central **Broker** process which helps manage interactive proof, and connection between front-ends and provers. The connection is a channel (typically a Unix pipe or socket).
- 2. PGIP components are designated as prover, display, or auxiliary (see Fig. 1).
- 3. Messages are classified: those which are sent *to* the PG Broker are given class pg. Messages which are sent to a proof assistant are given class pa, messages which are sent to a display are class pd.
- 4. PGIP communication proceeds by exchanging PGIP packets as XML documents belonging to the PGIP markup schema. A PGIP packet is contained in the pgip> element.
- 5. The interface sends command requests to the prover, and processes responses which are returned. Unlike classical RPC conventions which are single-request single-response, a command request may cause several command responses, and it is occasionally possible that the prover generates "orphan" responses which do not correspond to any request from the interface.
- 6. Each PGIP packet contains a single PGIP message, along with identifying header information. The PGIP message may be a *command request* or a *command response*.
- 7. The broker will only attempt to send commands to the prover when it has received a ready message. On startup, the prover may issue some orphan responses, followed by a ready message.
- 8. Each PGIP packet has the following attributes:
 - tag A message tag, for example, the name of the origin component.
 - id The session identifier of the originating component.
 - destid The session identifier of the destination component (for a response packet).
 - class The class of the message, as above.
 - seq A unique (for this session of this component) sequence number. Sequence numbers never decrease over time.
 - refid **and** refseq Both optional; if given, the session identifier, sequence number of a message this one refers to (see below).
 - origin Only the broker will set this attribute, either to broker to indicate messages generated within the broker, or to the component identifier of the originating component if it is relaying message, e.g. from a prover to a display.

In the following section, we describe the single messages in more detail. We classify the messages in three categories: common messages (all classes), those exchanged between prover and broker (classes pg and pa), and those exchanged between prover and displays (classes pg and pa).

2 Common Interaction

This section describes messages common to all three main classes of components.

2.1 PGIP and PGML markup

- 1. PGIP and PGML are separate document types:
 - PGML describes the markup for displayed text/graphics from the prover
 - PGIP describes the protocol for interacting with the prover
- 2. PGIP contains PGML in the same (default) namespace, so PGIP messages may contain PGML documents in certain places. PGML text is embedded with root components, which allows easy filtering by components concerned with display.

2.2 Prover to interface configuration

<usespgip>

• The prover reports which version of PGIP it supports (only between prover and broker).

<usespgml>

• The prover reports which version of PGML it supports (only between prover and broker).

<pgmlconfig>

- The prover reports its configuration for PGML.
- PGML can be configured for particular symbols. The prover reports the collection of symbols it will understand as input and emit as output, along with optional ASCII defaults. PGML symbol conventions define a large fixed set of named glyphs.

<hasprefs>

• The prover reports some user-level preference settings, each one in an <haspref> element, giving its type and possible a default value. A collection of *global preferences* (dynamic switches inside the prover) are reported by the prover in response to an <askprefs> message, or are volunteered by the prover during configuration. Further *object-specific* preferences may be reported inside <objtype> messages which appear as part of the <displayconfig> configuration.

<prefval>

• The prover reports a change in one of its preference settings, perhaps triggered by the interface.

<displayconfig>

• The prover specifies a *display configuration* which contains items to configure the interface to the running prover, which are described by the remaining elements listed below. In particular, the lexicalstructure elements describe the lexical structure of proof scripts for the prover, while the objtype and opn operations describe the types of values that the prover wants the user to manipulate.

<welcomemsg>

• A simple textual message to inform the user about the underlying prover process.

<icon>

an icon which is a Base64-encoded bitmap picture, representing the prover.

<helpdoc>

• An available item of documentation to make available to the user (e.g. in a menu). Includes either a URL or an argument for the viewdoc proof context command. There may be several or none.

<lexicalstructure>

- An element which configures (some part of) the proof script syntax. It may include any of the below elements:
 - keyword. Each keyword element specifies the word itself (word attribute), together with an optional category and long and short help texts.
 - * The category is used, e.g., for subdividing menus or for configuring more than one colour for keyword syntax highlighting. It is not used for parsing. Recommended categories are: major (the default if none is mentioned) for main keywords;
 - minor auxiliary keywords.
 - with language-specific additions.
 - * The shorthelp element gives a short tooltip-length help text for the keyword.
 - * The longhelp gives a larger paragraph-length help for the keyword.
 - stringdelimiter elements

Notice that the features of the lexical syntax which are supported by different displays may be affected by their individual capabilities (e.g., Emacs only allows one or two characters in comment-start and comment-end sequences).

<objtype>

- The prover specifies a basic object type it will let the interface manipulate.
- A type has a mandatory name attribute;
- it can have a description attribute, describing the type, and
- an icon which is a Base64-encoded bitmap picture (at the moment, the default and only format here are GIF bitmaps).
- optional preferences specified by a <hasprefs> element; these may indicate, for example, whether a theorem is flagged as being an introduction or elimination rule.
- Further, the types determine a hierarchical organisation of the prover objects; objects of each type may contain objects of other other types, as specified by the contains attribute.
- The following types are always predefined:
 - "toplevel" for toplevel objects;
 - "theory" for theory files;
 - "theorem" for theorems;
 - "comment" for comments.

theory contains theorem and theory. Provers are free to redefine these types, e.g. to define new icons.

<opn>

- opn are commands which combine object values of the prover, in a functional manner. The opcmd should be some text fragment which produces the operation. The operations could be triggered in the interface by a drag-and-drop operation, or menu selection.
- As a general convention, if several operations are possible to produce a desired target object, then the interface should offer them in the choice that they were configured.

2.3 Identifiers

The PGIP model accommodates *identifiers*, i.e. the ability of the prover to name objects. The protocol makes the following assumptions about identifiers:

- Each identifier has a type (see above).
- Provers can arrange identifiers in a hierarchical fashion, so the name of one identifier can be valid in the *context* of another identifier, as specified by the contains attribute on the types.
- Identifiers can be used in a proof by referring to their name, and they can be displayed.
- The prover has a certain amount of pre-defined identifiers available upon starting, and can define more identifiers during run-time.

<askids>

• Ask prover to display identifiers, possibly in a given context and only of a given type; prover should respond with setids or addids message.

<showid>

Ask prover to display value of an identifer. Prover should respond with showid message.

<idtable>

A list of identifiers of a given type, possibly in a given context.

<setids>

- Argument is a list of idtables.
- For each idtable, deletes previously known identifiers of that type and context, and add given identifiers.

<addids>

- Argument is a list of idtables.
- For each idtable, add given identifiers.

<delids>

- Argument is a list of idtables.
- For each idtable, deletes previously known identifiers of that type and context.

<idvalue>

Displays the value of a given identifier as a sequence of text of PGML packets.

3 Prover and Broker

This section describes the communication between broker and prover. The proof script commands are also handed on to the interface for display, but the interface is only supposed to use the markup to display structure.

3.1 Prover control commands

cproverinit>

Reset the prover to its initial state.

cproverexit>

· Exit the prover gracefully.

<startquiet>

• Ask the prover to turn off its output. This is intended to supress display of intermediate steps while processing a possibly large number of proof commands.

<stopquiet>

Ask the prover to turn on its output again.

3.2 Prover output

<ready/>

- The prover should issue a ready/ message when it starts up, and each time it has completed processing a command from the interface.
- The interface should not send a command request until it has seen a ready/ message. Input which
 is sent before then may cause buffer overflow, and more seriously, risks changing the prover state in
 an unpredictable way in case the previous command request fails.

<normalresponse>

- All ordinary output from the prover appears under the normalresponse element. Typically the output
 will cause some effect on the interface display, although the interface may choose not to display some
 responses.
- A PGIP command may generate any number of normal responses, possibly over a long period of time, before the ready response is sent.

<errorresponse>

- The errorresponse element indicates an error condition has occurred.
- The fatality attribute of the error suggests what the interface should do:
 - a nonfatal error does not need any special action;
 - a fatal error implies that the last command issued from the interface has failed (a recoverable error condition):
 - a panic error implies an unrecoverable error condition: the connection between the components should be torn down.
- The location attibute allows for file/line-number locations to identify error positions, for example, for when a file is being read directly by the prover.
- A PGIP command may cause at most one error response to be generated. If an error response occurs, it must be the last response before a ready message.

<scriptinsert>

- This response contains some text which should be inserted literally into the proof script being constructed.
- The suggestion is that the interface immediately inserts this text, parses it, and sends it back to the proof assistant to conduct the next step in the proof. This protocol allows for "proof-by-pointing" or similar behaviour.

<metainforesponse>

- The metainforesponse element is used to categorize other kinds of prover-specific meta-information sent from the prover to the interface.
- At present, no generic meta-information is defined. Possible uses include output of dependency information, proof hints applicable for the current proof step, etc.
- Provers are free to implement their own meta-information responses which specific interfaces may interpret. This allows an method for extending the protocol incrementally in particular cases. Extensions which prove particularly useful may be incorporated into future versions.

Here are some example message patterns allowed by the PGIP message model:

<pre>toprovermsg <ready></ready></pre>	<pre>toprovermsg <normalresponse></normalresponse></pre>	<pre>toprovermsg <normalresponse></normalresponse></pre>
:	<normalresponse> <normalresponse> <ready></ready></normalresponse></normalresponse>	<pre><errorresponse> <normalresponse> <ready></ready></normalresponse></errorresponse></pre>
	:	:

The *toprovermsg* is a message sent to the proof assistant and the responses are shown below. Responses all end in a ready message; the only possible exception is a panic error response, which indicates that the proof assistant has died (perhaps committed suicide) already.

3.3 Proof control commands

The PGIP proof model is to assume that the prover maintains a state which consists of a single possibly-open proof within a single possibly-open theory, see Section 3.4 for more explanation. We distinguish between **proper proof commands** which can appear in proof scripts, and **improper proof commands** which cannot.

In PGIP 1.0, proper commands were required to be interpreted by the theorom prover so they could be used to construct parts of proofs (e.g. the interface can provide an action for completing a proof). In PGIP 2.0 we rely on other mechanisms to construct proof script text, and proper commands are interpreted merely as markup which provides structure on a proof script document for the interface. The markup should be ignored by the prover when it processes a proper proof command. To simplify things for the interface, a proper proof commands may be wrapped in a <dostep> element which is ignored by the prover as well (and which is *not* allowed in markup for parseresult>).

Proper proof commands.

<opengoal>

open a goal in ambient context

cproofstep>

• a specific proof command (perhaps configured via <opcmd>)

<closegoal>

• complete & close current open proof (succeeds iff goal proven)

<giveupgoal>

close current open proof, record as proof obligation (Isar's sorry).

<postponegoal>

• close current open proof, retaining attempt in script (Isar's oops)

<comment>

• a proof script comment; text is probably ignored by prover

<whitespace>

• a whitespace comment; text must be ignored by prover and may be discarded

<litcomment>

• a literate comment which is never passed to the prover

<spuriouscmd>

a command which is ignored for undo purposes, and which could be pruned from a proof script (e.g. print x).

Improper proof commands.

<dostep>

• Used to issue a proper proof command to the prover, without passing in more specific markup. The prover should interpret <dostep> and any proper proof command simply by executing their contents.

<undostep>

undo the last proof step issued in currently open goal.

<redostep>

• redo the last proof step issued in currently open goal. Optionally supported.

<abortgoal>

give up on current open proof, close proof state, discard history.

<forget>

forget a theorem (or named target), outdating dependent theorems (or other elements).
 If theory name is omitted, we default to currently open theory. If ordinary name is omitted, default to whole theory. (Makes no sense for both names to be omitted). Optional type attribute is allowed for provers that have overlapping namespaces, that may allow forgetting different kinds of things within theories.

<restoregoal>

• re-open previously postponed proof, outdating dependent theorems. This is a context switch operation. Optionally supported.

Further notes:

- The improper proof commands are meta-operations which correspond to script management behaviour: i.e., altering the interface's idea of "current position" in the incremental processing of a file. The broker will enhance whatever native history management is supported by the prover, and try to exploit it.
- 2. In a later version, we may allow the prover provide a way to retain undo history across different proofs. For now we assume it does not, so we must replay a partial proof for a goal which is postponed.
- 3. We assume theorem names are unique amongst theorems and open/goals within the currently open theory. Individual proof steps may also have anchor names which can be passed to forget.
- 4. The interface manages outdating of the theorem dependencies within the open theory. By constrast, theory dependencies are managed by the prover and communicated to the interface.

3.4 File-level and theory-level commands

PGIP assumes that the prover manages a notion of theory, and that there is a connection between theories and files. Specifically, a file may define some number of theories. The interface will use files to record the theories it constructs (but may choose to only construct one theory per file).

PGIP assumes that the proof engine has four main states, which are nested:

top level inspection and navigation of theories only; no focus of active development.

open file a file is open for processing; we may declare theories now and other items which appear within files.

open theory a theory has been opened for construction; we may declare new definitions, types, and other commands which appear at the theory level. The prover may record an undo history of theory-level element declarations, but discards this history when the theory is complete.

open proof a proof has been opened for construction; we may issue proof steps which aim to complete the proof. The prover records an undo history for each step, but discards this history on proof completion.

This model only allows a single open item at each level (file, theory, or proof). Nonetheless, it should be possible for the interface to provide extra structure and maintain an illusion of more than one open item, without the prover needing to implement this directly. This can be done by judicious opening and closing of files, and automatic proof replay. Later on, we may extend PGIP to allow multiple open proofs to implemented within the prover to provide extra efficiency, to avoid too much proof replaying.

Similar to proof commands, theory and file commands divide into proper commands, which may appear in proof scripts, and improper commands, which may not. Proper file commands are treated as markup on parsed proof scripts, just as proper proof commands are.

Some improper commands are optional. Commands which are not supported in general should not be included in <acceptedpgipgelems> for the component. Where a command is not possible in a particular case, an error message should be given.

PGIP supposes that the interface has only partial knowledge about theory construction, and so the interface relies on the prover to send hints. Specifically, to help manage file-level control, there are are two information response messages which may be sent *from* the prover which help connect to the prover's internal file management system (if it has one).

Proper File Commands.

<opentheory>

begin construction of a new theory.
 Attributes may provide the ancestor theory names.

<closetheory>

• complete construction of the currently open theory. When executed this discards any theory-level undo history.

<theoryitem>

 an item in a theory other than a binding or proof, for example type definition and data type declarations.

Improper File Commands.

<doitem>

Process the given proper theory command (without passing in markup)

<undoitem>

• Undo the last step during theory construction (or the given named target, if possible).

<redoitem>

• Re-process the last undone theory-level item, if possible.

<aborttheory>

Give up on the currently open theory (undo to before theoryopen, discarding history).

<retracttheory>

• Remove the named theory, and any dependent theories.

<openfile>

Signal that the named file is being opened for constructing a proof text interactively.
 The prover may pay attention to this message if it tracks processed files: the file should not be one which is already processed.

<closefile>

Signal that the currently open file has been completely processed.
 The prover may pay attention to this message if it tracks processed files. The file should now be considered fully processed, as if the prover had read it directly.

<loadfile>

• Read a file directly for processing in batch mode.

The prover may load any required files automatically, but should indicate when this happens by sending appropriate <informfileloaded> messages to the broker.

<retractfile>

Undo a processed file. Optionally supported.
 Only relevant if the prover tracks processed files. The prover may retract any files which are dependent on the given one, but if it does so, it should inform the broker of this by sending appropriate <informfileretracted> messages. Files which are not retracted automatically by the prover will be retracted by the broker.

<changecwd>

change prover's current working directory.
 In case the prover may read subsidiary files, the interface can set the directory that the proof script under construction is destined for. Normally this would be the path of the URI given in an openfile command which might precede openfile.

<systemcmd>

• An escape which allows to send an arbitrary command to the prover. A certain security hole.

File loader information responses.

<informfileloaded>

prover informs interface a particular file is loaded.
 When the interface asks for a file to be loaded, or when some proper proof script command triggers file loading, a number of <informtheoryloaded> responses can be sent from the prover. These indicate dependency of the loaded file on whatever caused the loading, and also suggest that the loaded files should be considered processed by the prover.

<informfileretracted>

prover informs interface a particular file is outdated.
 Conversely, when the interface asks for a file to be retracted, the prover may automatically retract dependent files. If it does so, it should inform the broker with <informfileretracted> messages.
 The broker will retract remaining dependencies.

3.5 Parsing

Proof scripts are written in the prover's native language. By *parsing*, we mean enriching them with PGIP markup to make their structure explicit. The component which does the parsing need not always be the prover, it could be an auxiliary component which filters out the parsescript> requests from the input stream and answers them.

<parsescript>

• Requests the prover to parse one or more command lines. (This can be a whole proof script.) Optional attributes are the starting position; these are for error reporting, such that <errorresponse> answer can carry the correct location wrt to the original source.

<parseresult>

Returns the result of a parsing request.

<singleparseresult>

• A single parse result is an <unparseable> element, or an <errorresponse> containing error messages, or a *proper script command*, which is either a proper proof command, a proper file command, or a delimiter (<openblock>/<closeblock> below).

One <parsescript> must result in exactly one <parseresult>. There is an invariant that by discarding all markup on the result of the parse, we get back the original proof script. The prover may leave out text when returning the parsed elements (these are then considered unparseable), but the *order* must be maintained.

<unparseable>

• Returns text the parser can not make head or tails of.

<openblock>

Opens a layout block. The proof script can have layout structure annoted with basic <openblock> and <closeblock> elements. A basic <openblock> element has no attributes except optionally a name. This block structure suggests intendation or a tree-like structure for layout purposes. A basic <openblock> is taken to be associated with the immediately preceding document element; block delimiters themselves are empty.

Blocks can alternatively be treated special positions in the document which may be replaced by text in document-based development. These blocks are indicated by cpenblock with a non-empty metavarid or objtype element. The meta-variables is used to communicate a document position back to the prover; an object type allows the interface to replace the contents of the document element. These kind of blocks are *not* used for layout.

<closeblock>

• Closes the matching block. Once parsing has been completed, there will be a matching <closeblock> for each <openblock>, but in a single cparseresult> this may not be the case for layout blocks, as we may only parse part of a document. For document element blocks

4 Broker and Display

This section describes the communication between broker and display (classes pg and pd). In the following, **display messages** go from the broker to the display, and **display commands** go from the display to the broker.

4.1 The PGIP edit-prove cycle

The PGIP system architecture supports an edit-prove cycle in which the user can interactively edit and construct proof scripts, residing in files.

Internally, the broker component is responsible for the actual handling of the source documents. The user editing commands are translated into PGIP display commands (class pd), which are sent to the broker for the actual editing.

For the display, the source is broken up into *objects* [**FIXME**: bad name, heavily overloaded. What about items, units or atoms?] which contain a PGIP element each. Each object has an identifier, which the display has to keep track of, as subsequent edit and change commands pertain to the object identifier.

Each object has a status, which ranges over five possible values (see Fig. 2). The different transitions between the objects are a refinement of the script management as implemented by Proof General. The object status can change by the results of the interaction with the system. After editing, an object becomes either *parsed* or *unparseable*; after being processed by the prover it becomes *processed* and can become *outdated* later on. Note that while being processed the object cannot be edited; if it has been processed it needs to be outdated first. The unparseable status is for objects which cannot be parsed (because they are syntactically malformed) but which we still need to be part of the proof script.

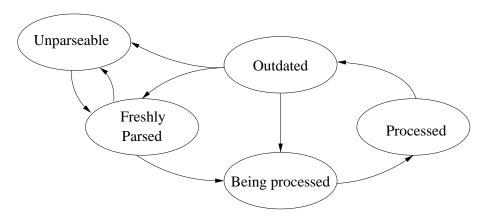

Figure 2: Object Status Transitions

Here is a typical edit-prove cycle:

1. Loading a file.

- (a) The user wants to edit an old file and selects the corresponding menu button or cryptical key sequence. This results in the display sending a <loadfile> message to the broker.
- (b) The broker actually reads the file, locks it while it is being edited, and sends it to the prover to be parsed (with a parsescript> request).
- (d) The broker now sends a series of <newobj> messages to the display. This will actually display the source file.
- (e) To save a file, the display sends a <savefile> message, which causes the broker to assemble the source file and write it to a file.

2. Editing.

- (a) The user can edit an object. In a graphical display, the user may actually see the object structure as it is graphically represented, but in a pure textual interface (such as the revered Emacs editor) only text can be edited. In any case, the display must keep track of the positions of the object in the display, such that any edit operation on part of the user can be translated into a <editobj> request being sent back to the broker. <editobj> contains a range of object identifiers, and the new text to be inserted for these identifiers.
- (b) The broker now sends <delobj> messages for all objects in the span being edited, signalling to the display that they are not needed any more.
- (c) The broker decides wether this edit is *allowed* or not: it is always allowed for comments, outdated and unparsed objects, never allowed for objects being processed (and if possible, the display should not allow it to start with), and for processed objects it corresponds to a request to outdate the object, followed by the actual edit. If editing is not allowed, the broker sends an error message to the display, and <newobj> messages which reinstate the original content. [FIXME: this is debatable, as the user loses his changes? Should not have made them in the first place?]
- (d) If editing is allowed, the text is sent to the prover to parse. We make the assumption here that the prover does not need a context to parse single commands like this, as this would considerably complicate the protocol; this seems a reasonable assumption as no typecheck etc. needs to be performed. The prover either returns a parseresult> element if the parse is successful, or an error message otherwise which is sent on to the display.
- (e) If the broker received an error message, it sends a <newobj> message inserting an unparseable object. The user can then try again.

3. Proving: processing a file.

- (a) Processing a file means that the user requests the status of a particular object to be changed (e.g. to processed to make it up-to-date, or to outdated if it needs to be edited). The display sends a <setobjstatus> request to the broker.
- (b) The broker checks the status of the object, and translates the request into a number of PGIP commands sent to the prover. (To bring a single object up-to-date, an arbitrary number PGIP commands may be needed, e.g. a long proof script be worked through).
- (c) The resulting object changes (not only for this object as other objects may change status as well, e.g. objects this depends on being brought up-to-date) are sent back to the display as <objectstatus> messages. The last one of these message will change the status of the required object, unless an error has occured.

4.2 Control Messages

Attribute: prvid

• A unique *prover identifier*. Once a prover has started, it is referred to by a such an identifier. The Broker can handle more than one prover at a time, but each source file can only contain theories and hence objects from a single prover.

<componentspec>

- specifies a PGIP component. It gives a unique identifier (e.g. "isa2004-HOL", a textual name under which is visible and meaningful to the user (e.g. "Isabelle 2004/HOL"), the type (allowed are provertype, displaytype, and auxiliary) and specifies how to connect to or start it.
- Only the broker knows the specifiation of the components. The present assumption is that the broker reads a configuration file containing a list of <componentspec> on startup; this should later be extended to allow dynamic configuration, e.g. by allowing for new components to announced to the broker.

• On starting a display, the broker will send it a

brokerstatus> message (containg in particular a list of known provers) as part of the initial configuration sequence.

Display Commands:

<launchprover>

 request a new prover to be launched; attribute componentid is the component identifier for a known prover.

<exitprover>

requests prover to be stopped; attribute is the prvid.

<restartprover>

• requests prover to be restarted; attribute is the prvid.

<shutdownbroker>

• requests broker to perform shutdown; optional attribute is force. The broker will not shut down if there are still unsaved changes in source files, unless 'force' attribute is given (with value true).

<brokerstatusquery>

• request broker status information.

Display Messages:

 drokerstatus>

• status information from broker, containing known provers, running provers, and some textual information;

overavailable>

• a new prover is available under name and componentid given as attributes (must be launched before use.)

• a new prover has just started under proverid given as attribute.

The proverid is the same as the componentid used to start this prover. Thus, we cannot run multiple copies of the same prover concurrently.

overstatus>

- prover status has changed. Displays are urged to display ready/busy information, as provers may diverge and users will want to notice.
- Attributes:

prvid unique prover identifier proverstatus can be busy, ready or exitus

4.3 File Handling

Attribute: srcid

A unique source file identifier. The broker can handle more than one source file, and so must the
display. The source file identifier is assigned by the broker once the file has been loaded or created,
and referred to when saving the file, or inserting new objects. This corresponds, very roughly, to an
Emacs buffer.

Display Commands:

<loadparsefile/>

- user requests an existing source file to be loaded into a specific prover.
- Attributes:

url URL of file to be loaded. (The Broker will not understand anything else than the file scheme for a while.)

prvid identity of prover which should read the file.

<dispopenfile/>

- user requests a new source file to be created.
- Attributes:

url URL of file to be created.

overwrite overwrite if file exists (otherwise gives an error).

prvid identity of prover which the source file is to be created for.

<newfilewith/>

- user requests a new source file to be created, with given text content. In contrast to dispopenfile, the file may be written out later, and the user may not commit to any file name yet. In that case, a subsequent savefile must give a URL.
- Attributes:

url URL of file to be created.

prvid identity of prover which the source file is to be created for.

<savefile/>

- user requests changes to be committed
- Attributes:

srcid unique source file identifier

url (optional) URL of where to save; default is to save where it has been created or loaded it from.

<discardfile/>

- User wants to discard changes to this file.
- Attributes:

srcid unique source file identifier

Display Messages:

<newfile/>

- The broker has created a new file or loaded an old file, and announces the new source file identifier.
- Attributes:

srcid unique source file identifier

<filestatus/>

- Informs the display that the status of a file has changed. The interface can use this to display 'needs-save' information.
- Attributes:

srcid unique source file identier

filestatus new status: saved, changed, or discarded.

datetime Time and date in XML Schema format (briefly, CCYY-MM-DDThh:mm:ss followed by Z for Zulu time or a timezone offset like -01:00). It indicates the time the status change took effect (in particular, when a file was written).

• A discarded message is the last in which this srcid will be used.

4.4 Object Management

Attribute: objstatus

- Attribute which can have five possible values:
 - unparseable
 - parsed
 - being_processed
 - processed
 - outdated
- The interface should if possible stop the user from editing objects which are being_processed, as the broker will reject these edits.

Attribute: objid

• A *unique object identifier*, which is unique for this broker during this session, across all objects in all source files and for all provers.

Display Messges:

<newobj>

• The broker has created a new object and requests it being displayed. The contents of this element is a proper script command, and the attributes are as follows:

srcid identifies the source file in which this object is being inserted.

objid unique object identifier, to be used in subsequent editing operations;

objposition optional objid of object before which this object is inserted. If empty, insert at the end of the current text.

 $\verb"objstatus" object status" (see above; freshly created objects are either of type \verb"parsed" or \verb"unparseable");$

objparent optional objid of a parent object, in case the display wants to display objects hierarchically. These are generated from the block structure given by the parser, and are only for layout; they carry no semantic meaning.

<delobj/>

- Signals that the broker has deleted all references to this object identifier, and requests display to delete it if it has not already done so.
- Attributes:

srcid unique source file identifier objid unique object identifier

<objectstatus/>

- State of this object has changed in the broker
- Attributes:

srcid unique source file identifier objid unique object identifier objstatus new object status.

Display commands:

<editobj>

- The user has edited one or more objects. The content of this message contains the edited text.
- Attributes:
 - editfrom (optional) unique object identifier of object where the editing started; if not given edit starts from first object.
 - editto (optional) unique object identifier of object where the editing ended; if not given edit ends with last object.
 - srcid (optional) identifies the source file in which the objects are edited; can be omitted if one of editfrom and editto is given.

<createobj>

- The user has entered text which is not an edit of existing objects; in other words, the user requests new objects to be created. The content of the message contains the entered text.
- Attributes:

srcid (optional) identifies the source file in which this object is created.

objposition (optional) unique object identifier before which the new objects are to be inserted. If empty we add resulting objects to the end of the buffer.

At least one of srcid or objposition has to be given. Since the object determines the source file, if objposition is given, it takes precedence over srcid.

<setobjstatus/>

- The user has requested the status of this object to be changed.
- Attributes:

objid unique object identifier objstatus new object status. Only processed and outdated status can be requested.

5 PGML markup language (v 2.0+)

PGML is a simple markup language for annotating prover input and output text. Annotations can be used to provide pretty printing hints (blocks and line breaks), or additional structure on already pretty-printed text. The markup is intended to be further transformed (e.g. by system-specific stylesheets) to produce HTML or other display forms.

PGML is not intended to be a complete language for fully flexible page layout. Instead, if needed, more complex layout instructions can be embedded in another XML language using the <embed> element: for example, MathML for math fragments or HTML for ready-rendered web pages.

Text is split into *terms* which can have a nested subterm structure. A <subterm> is a position for attaching annotations of various kinds. Annotations can include:

Attribute: subterm

name a user-level global identifier

objtype (obj)type information

place placement directives (sub, super, above, below)

decoration decoration hints for fonts (bold, italic) or colouring (e.g. standard *error*, *warning* and *information* attributes for markup with red/yellow/blue squiggles)

action actions for activation (e.g. triggering a context menu, button to show a button, or toggle for folding).

pos a position pointer to the some content form (e.g. true abstract syntax before rendering) which is used to communicate back to the prover (also used for menu request or button pushing).¹

xref a cross reference to a defining declaration (typically a file URL with a numerical dotted fragment for the line and column number, e.g. file:///home/da/Test.thy#15.55.

Leafs of terms can be strings, <atom> elements or (atoms containing) <sym> elements. The <sym> element is a named reference to a symbol (or composite symbol) which has been configured in a symbol configuration specific to the prover/display.

Pretty printing <box> annotations are included, modelled after those of BoxML in GtkMathView (see http://helm.cs.unibo.it/mml-widget/qna.html).

See comments in the schema for more information.

<pgml>

This element encloses a PGML document which is displayed in a window.
 Attributes:

area for output markup, used to indicate a window where the document should appear.

version version of PGML this document uses.

systemid System identifier token. This can be used by the display to control the interpretation of prover-specific style elements.

The version and systemid attributes will not normally be used by the prover, since the surrounding PGIP packet should determine these. The broker may add them for the purposes of sending on to other components.

¹TODO: not yet harmonised with PGIP messages

Attribute: displayarea

- PGIP assumes a display model which contains (at least) two display areas: the **message** area and the **displayarea**.
- Typically, both areas are shown in a single window. The display area is a possibly graphical area whereas the message area is a scrollable text widget that appears (for example) below the display area.
- The interface should maintain a display of all message area output that appears in response to a particular command. Between successive commands (i.e. on the first new message in response to the next command), the interface may (optionally) clear the message area.
- The interface should simply replace display area output whenever new display area output appears.
- Additional features may be desirable, such as allowing the user to keep a history of previous displays somehow (display pages by forwards/backwards keys; messages by text scrollbar).
- The interface is free to implement these displays in different ways, or even supress them entirely, insofar as that makes sense.

A Schemas for PGIP and PGML

   # Notes on pgipchoice:
471
   # 1. Choices must not be nested (i.e. must not contain other choices)
472
   # 2. The description attributes for pgipbool, pgipint, pgipstring and pgipconst
473
474
         are for use with pgipchoice: they can be used as a user-visible label
475
         when representing the choice to the user (e.g. in a pull-down menu).
      3. A pgipchoice should have an unambiguous representation as a string. That means
476
    #
    #
         all constants in the choice must have different names, and a choice must not
477
    #
         contain more than one each of pgipint, pgipstring and pgipbool.

7
8
   # Status: Complete, prototype.
9
   #
10
   # This is a simple markup language for annotating prover input and output
11
   # text. Annotations can be used to provide pretty printing or additional
12
   # structure on already pretty-printed text. The markup is intended to be
13
   # further transformed (e.g. by system-specific stylesheets) to produce
14
   # HTML or other display forms.
15
16
   # For additional commentary, see accompanying commentary document
17
     (available at http://proofgeneral.inf.ed.ac.uk/kit)

60
61
   ## An annotated subterm. This may be used to:
62
63
   ## - subdivide large displays (e.g. goal state by subgoals, assumptions)
64
          using the kind and parameter tokens (system specific interpretation);
65
   ## — mark an identifer or term with an objtype (and perhaps a global name);
66
```

```
## - decorate a region with a bold, italic, or other highlight (e.g.,
67
68
           to markup error/warning/info areas with squiggles red/yellow/blue).
    ## - reference to a content model with position annotations
69
    ## — indicate an action such as a system—specific menu, folding ("toggle")
70
           or render a button
71
    ## - give a cross reference to the defining point of some text
72
    ##
          (e.g. file URL with line.column fragment)
73

130
131
132
133
   ## Symbol configuration
134
```

135 ##

```
## The sym element can be rendered in three different ways.
136
    ## in descending preference order:
137
138
    ##
    ## 1) one of the previously configured alternatives for the symbol,
139
          available in a prover-specific configuration, see below.
    ## 2) the PGML symbol given by the name attribute, if one of
141
          standard (TeX-ish) names given elsewhere (deprecated).
142
    ## 3) the text content of the SYM element, if non-empty
143
144
    ## The symbol configuration allows flexible choice between
145
   ## different renderings.
146
147
148
    ## A configuration of PGML is a sequence of symbol configurations
149
    pgmlconfiguration = symconfig*
150
151
152
   ##
   ## A symbol configuration provides:
153
   ##
154
   ##
        a (unique) symbol name, used in the <sym> element
155
   ##
        a family name (user documentation only)
156
        a unicode character sequence
   ##
157
        an HTML alternative using HTML entities (in plain ASCII)
   ##
158
159
        a plain text alternative for impoverished ASCII displays
160
   ##
        a token text which can be used in the document in place of the unicode sequence
161
   ##
          to store files in a poorer ASCII/latin/other encoding
        a typing shortcut that may be supported by editors in displays
162
    ##
        an xml rendering (in some other XML schema)
163
   ##
   ##
164
   ## e.g.
165
   ##
166
   ## <symconfig name="Forall" family="Symbols" unicode="
                                                               " shortcut="all "
167
                  html="% forall;" token="\ < forall > " alt = "ALL" />
   ##
168
   ##
169
   ## Symbol configurations are prover specific. They may be shared
170
    ## between displays, although different displays may use different
    ## parts of configurations.
172
173
